What turns up when AI agents check the foundations of fossil science?

Barry W. Brook (University of Tasmania), prepared with Claude (Anthropic) and Codex (OpenAI). Draft of 12 November 2026; a plain-language summary of a living research repository, https://github.com/BWBrook/eprp.

The puzzle

Studies of the fossil record rarely start from the rocks. They start from shared resources: databases of fossil finds, data files published with papers, geological time scales, maps of past continents, and software that turns it all into rates of extinction and diversity. Each is built by someone else and changes over time, so a problem in one can travel quietly into the studies that use it. Checking them means copying each resource, finding cases where the right answer is known, and comparing: slow, detailed work across a whole field's toolkit.

What we did

Two AI systems, working with one scientist, spent a month building a research program on the fossil record. Along the way they copied databases, tested software against known answers and recomputed published numbers, logging 189 candidate findings. We chose the twelve that matter most for what a researcher would conclude and re-checked each from fixed, checksummed inputs. Every result is recorded with the command that reproduces it.

What we found

1. **Databases can lack records that a study deposited.** About one in five of the 368,760 mollusk records in one recent study's data file were absent from the public Paleobiology Database as it stood on 23 October 2026.
2. **Ages can shift, or disagree with their own sources.** Between two archived downloads of that database, the most common starting age of 460 time intervals changed. In a microfossil database, 4,111 of 56,387 stored ages differed from those implied by its own reference points.
3. **Software can be wrong, or mean something narrower than expected.** One package gave the wrong age to 3,972 of 8,282 test points, by up to 3.0 million years. Another compared numbers as

words, so a difference of 100 passed a threshold of 5 unflagged.

4. **Published numbers can fail recomputation.** A printed probability of about one in three thousand trillion is about one in three (0.316) under the test the paper describes. Two published spreadsheets differ from their source files in 2,967 and 220 rows.
5. **Known-answer tests show where methods hold and where they slip.** A long-established method for bounding when a species disappeared covered the truth in 1,909 of 2,000 simulated cases; a widely used tool's preservation-rate ranges covered it in 33 of 50, against the 95% they promise. Three maps of past continents placed the same sites a median of 13.6 degrees of latitude apart 400 million years ago.

What it means

AI agents can check the foundations of fossil science systematically, and what they find is specific enough to act on: record download dates and versions, compare more than one map of past continents, recompute a number before building on it, version database changes, and test software against known answers. The agents' own mistakes were caught the same way: re-checking corrected the first account of six of the twelve cases.

Limits

These twelve examples were chosen for their consequences, so they say nothing about how common such problems are. We did not rerun the studies that used these resources, so whether any published conclusion changes is open, as are the causes of the database differences. The people responsible for each resource had not yet been contacted, and nothing here compares AI checking with careful human checking.

How this work was done

OpenAI's Codex re-checked every finding, built the record of results and reviewed the wording. Anthropic's Claude compiled the candidate findings, chose the twelve cases, drafted this summary and designed the graphical abstract. Barry Brook guided the program and decides on release and on contact with the people responsible for each resource. Every number traces to a recorded command in the public repository.
